ABSTRACT

Background: Brain injury that occurs during the perinatal period is one of the most commonly recognized causes of severe, long-term neurological deficits in children often referred to as cerebral palsy (CP) that affects approximately 2-3 per 1000 school-aged children. The aim of this study was to detect the validity of urinary uric acid /creatinine ratio in the identification of perinatal asphyxia and its role in grading asphyxia according to severity of hypoxic ischemic encephalopathy. Patients and methods: This study was prospective study carried out at neonatology unit or delivered at Gynecology department of Zagazig university hospitals during a period of one year from July 2020 to July 2021. included 48 newborns with hypoxic ischemic encephalopathy. divided into Two groups; each group included (24) patients group I: 24 babies with perinatal asphyxia or group II: 24 healthy babies (with gestational ages and weights matched to cases. The primary outcome is determining the values of UUA/Cr in newborns with hypoxic ischemic encephalopathy and its relation with different stages of HIE. Results: Urinary uric acid/creatinine ratio was significantly higher in cases as compared to controls and was significantly higher in preterm babies when compared to full-term ones (this was applied for both cases and controls). Moreover, significant difference in UA/Cr ratio in comparing the mild, moderate and severe groups of HIE. Conclusion: We found that UA/Cr ratio level is increased in the asphyxiated newborns in comparison to normal healthy newborns.

I. INTRODUCTION

Perinatal asphyxia is still one of the significant causes of mortality and long term morbidity in spite of major advances in perinatal medicine. Failure to initiate or sustain respiration after birth” has been defined as criteria for the diagnosis of asphyxia by WHO(1).

Perinatal asphyxia results in hypoxic injury to various organs including kidneys, lungs and liver but the most serious effects are seen on the central nervous system(1).

Anyway, asphyxia is considered one of the most preventable causes of morbidity and mortality so many asphyxiated babies might profit from appropriate and timely treatment and resuscitation when asphyxia is properly diagnosed(2).

It has been established that an Apgar score at 5 min is a better tool than 1 min score for the assessment of newborn. However, the Apgar score is an expression of the infant’s physiological conditions and includes subjective components(3).

The limitations of Apgar score have prompted researchers to explore into other molecular markers of organ damage. Studies suggest role of urinary uric acid/creatinine ratio in asphyxiated babies, oxygen deficiency increases the level of hypoxanthines and uric acid due to degradation of purines which are important sources of free radicals which cause hypoxic brain injury(4). This study aimed to detect the validity of urinary uric acid/creatinine ratio in the identification of perinatal asphyxia and its role in grading asphyxia according to severity of hypoxic ischemic encephalopathy.
II. PATIENTS AND METHODS

This study was carried out on 48 neonates admitted to neonatology unit or delivered at Gynecology department of Zagazig university hospitals during a period of one year from July 2020 to July 2021. Written informed consent was obtained from all participants parents and the study was approved by the research ethical committee of Faculty of Medicine, Zagazig University. The work has been carried out in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki) for studies involving humans.

Inclusion criteria: Apgar score at 1 and 5 minutes ≤ 3. Umbilical cord arterial pH < 7.2. Umbilical cord arterial base deficit > 10 mM/L. Postnatal clinical manifestations of CNS insult (e.g. seizures, lethargy, Coma, abnormal tone and reflexes).

Exclusion criteria: Cases of oliguria: urine output below 0.5 ml/kg/hour (estimated after the 2nd day) or abnormal renal functions (serum creatinine level above 1.25 mg/dl). These neonates were excluded to avoid misleading uric acid levels. Neonates who started oral milk feeding, to avoid protein diet effect on increased uric acid excretion level. Cases with congenital anomalies.

Asphyxiated cases (group A) were furtherly subdivided according into three clinical stages of hypoxic-ischemic encephalopathy (HIE):

- HIE stage I (group 1): included hyperalertness, hyperreflexia and tachycardia.
- HIE stage II (group 2): included lethargy, hyporeflexia, bradycardia, hypotonia, weak suckling and Moro reflexes, and convulsions.
- HIE stage III (group 3): included stupor, profound hypotonia hypothermia and absent sucking and Moro reflexes.

All patients were subjected to detailed history taking, General and systemic examination including Vital signs, Apgar scoring at 1, 5 and 10 minutes. Assessment of gestational age using new Ballard scoring System (5). Anthropometric measures at birth including baby's weight, length and head circumference. Meticulous organ system examination with special emphasis on neonatal reflexes, muscle tone and state of consciousness.

Laboratory investigation included:

Serum creatinine level: From postnatal venous sampling (Cases with laboratory evidence of renal impairment were excluded from the study). Cord arterial blood gases and acid base balance: Were determined. At delivery, the umbilical cord was doubly clamped before the baby's first cry. Umbilical artery blood was collected into heparinized syringes for determination of pH, Pa O2, Pa CO2, HCO3 and base deficit within 15 minutes of sampling using Rapid Lab.860.

Serum sodium and potassium levels by Ion selective electrode method using Clinical Flame Photometer and the samples used were the serum remaining after blood ultra-centrifugation.

Urinary uric acid First voided urine sample after admission was obtained through application of a urine bag. The timing of the sample varied from one baby to another with a range of 2 to 24 hours.

Determination of urinary uric acid was done by an enzymatic colorimetric test (uricase-PAP) by Spinreact.

Test Principle: uric acid was oxidized by uricase to allantoin and hydrogen peroxide which under the influence of POD oxidized DCBS and 4-AP to form a red quinoneimine compound.

Uric acid + 2H2O2 → uricase Allantoin +CO2 +2H2O2
2H2O2 +4AP + DCBS → POD Quinoneimine + 4H2O

The quantity of this red quinoneimine is proportional to the uric acid concentration. Urinary creatinine by using Jaffe method without de-proteinization.
Measurements were done against air, at wavelength Hg 492nm and spectrophotometer 490.

Calculation: Concentration of creatinine in the sample was calculated:

Creatinine conc.(mg/dl) = 100 x A sample/A standard.

Radiological examination: MRI examination was done at Radiology Department Zagazig University Hospital.

Examination was done only to cases with moderate and severe HIE. CT was done during the first week of life.

Statistical Analysis

The collected data were computerized and statistically analyzed using SPSS program (Statistical Package for Social Science) version 27.0. Qualitative data were represented as frequencies and relative percentages. Chi square test was used to calculate difference between qualitative variables. The threshold of significance is fixed at 5% level (P-value). P value of <0.01 indicates highly significant results.

According to the studied groups, Table 4 showed that at cut off >2.13 UUA/creatinineratio had sensitivity of 91.7%, specificity of 83.3% and accuracy of 87.5% in diagnosis of asphyxia. While according to the cases group, shows...
that at cut off >2.13 UUA/creatinine ratio had sensitivity of 85.7%, specificity of 76.5% and accuracy of 79.2% in diagnosis of severe asphyxia.

IV. DISCUSSION

Brain injury that occurs during the perinatal period is one of the most commonly recognized causes of severe, long-term neurological deficits in children often referred to as cerebral palsy (CP) that affects approximately 2-3 per 1000 school-aged children\(^6\).

The overwhelming evidence suggests that the proportion of CP attributed to birth asphyxia represents about 10-20% of all cases\(^7\). However, this is the most relevant and important group of infants with CP because therapeutic strategies aimed to minimize or prevent cerebral injury are feasible\(^8\).

The diagnosis of perinatal asphyxia, however, is often inexact and objective means of assessing its severity are controversial or often lacking.

The use of fetal heart monitoring, blood gas analysis, Apgar score and other indicators of tissue damage have all failed to predict late neurological sequelae accurately \(^9\).

Our current study aims at the detection of urinary UA/Cr ratio in asphyxiated neonates and its validity in assessing severity of HIE and its correlation to prognosis.

Our study was conducted on 48 neonates, 24 asphyxiated and 24 non-asphyxiated taken as controls.

Our study also agrees with, Changlian et al.\(^10\), found no significant sex difference between HIE patients and controls. Also our study agrees with Ballard et al.\(^5\) study.

However, male sex predominance among newborns with perinatal asphyxia was evident in many previous studies, Majeed et al.\(^11\)\(^\) and Courtney et al.\(^12\), who found that approximately 60% and 64% of asphyxiated neonates respectively were males. This finding was explained by Greenough et al.\(^13\) who found that male fetuses are known to have lower catecholamine levels than their female counterparts and so are less protected against intrapartum hypoxia and its sequelae. Furthermore, Lang and McCullough\(^14\) who were studying the different pathways of ischemic neuronal cell death and their relevance to sex reported that females are more protected from hypoxia than males by the neuroprotective effects of estrogen (17β estradiol or E2) against ischemic insults. McCullough and Hurn\(^15\)\(^;\) Brann et al.\(^16\), found that there is more genetic predisposition to hypoxic-ischemic injuries in males compared to females.

Our study demonstrated no significant relation between gender difference and brain insult, this is in matching with the author\(^17\).

Increasing risk of asphyxia in prematures Nelson et al.\(^18\) recorded that preterm newborn mammals exhibit greater resistance to cerebral damage from hypoxic-ischemic insults than term newborns.

But this is controversial to Song et al\(^19\), who recorded higher incidence of asphyxia in deliveries ending prematurely.

This difference may be explained by less liability to birth trauma and obstructed labour in preterm (LBW). Anyhow, a study on larger number of cases should be done to clarify this point.

In our study mean birth weight difference was insignificant between cases and controls (1.84±0.30 in the former versus 1.99±0.24 in the later). This is in agreement with Pattrakul et al\(^20\).

Anne Lee et al\(^21\) who did not record significant difference in birth weight between asphyxiated and normal newborns. On the contrary Chandra et al.\(^22\) found that asphyxia is more incident in low birth weight and explained this by the reduced ability of LBW infants to adapt during asphyxia due to low metabolic reserves.
Apgar score at 5 min.(reflecting severity of asphyxia despite resuscitative measures) was lower in asphyxiated as compared to controls (2.46 ± 0.66 versus 7.04 ±1.16). This is in agreement with Ehrenstein et al(23), Salustiano et al.(24), (Biswas et al(3) who stated that 5(not 1) min. Apgar score is valid as an index for asphyxia.

On the contrary, Sitthivuddhi et al.(25)found that normal umbilical pH (thus excluding asphyxia) occurred in 77.8% of depressed newborns (low Apgar)1% of vigorous babies had umbilical cord arterial acidemia. The mean cord arterial pH was significantly lower in cases than in controls. This is in agreement with Fatrakul et al. (20) who stated that profound acidemia is the hallmark of asphyxia. Finer et al. (26) found that only pH values below 7.04 denote neurologic compromise. Moreover, stated that normal pH correlates with absence of any immediate or long-term neonatal morbidity.

Also, Goodwin TM et al. (27) found that HIE occurred in 12% of their studied group at low pH of (6.9-7.0).

Base deficits showed significantly higher levels in cases as compared to controls (7.19± 0.05 versus 7.34±0.17). This is in accordance with Low (28) who reported high values of base deficits moreover stated that a value of 10-19mEq/L does not have any sequelae and at least values of more than 20 mEq/L are required to cause neurological damage.

While many clinical and laboratory criteria are used to identify asphyxia, none, either alone or combined, is a definite diagnostic index of the occurrence and the severity of perinatal asphyxia.

During asphyxia, inspite of the fall in blood and tissue pH and partial oxygen pressure, the tissue oxygen consumption persists leading to further decrease in PaO₂ (29). Anaerobic metabolism ensues with the resultant production of large quantities of metabolic degradation products such as lactic acid. In parallel, ATP degradation is accelerated with increase in the formation of hypoxanthine (30). In cases of continuing hypoxia, hypoxanthine is degraded by xanthine oxidase to xanthine and uric acid (31).

As uric acid is the main metabolite of ATP degradation, so increased excretion of uric acid can be caused by metabolic changes reflecting cellular hypoxia or by renal changes (32).

This study shows that the urinary UA/Cr ratio in the early void urine sample is elevated in asphyxiated neonates as compared to normal(2.61±0.46 in the former versus 1.20±0.87) in the later. This is in agreement with the results of Bhongir et al(33) and Basu P et al(34), but they conducted their work only on full term babies.

Moreover urinary UA/Cr ratio was found to be significantly correlated with the clinical staging of HIE according to Sarnat HB and Sarnat MS (35) (the highest the ratio the more the severity of HIE). This is in agreement with the results of Chen et al(36).

In our study it was found that urinary UA/Cr ratio correlated significantly (r= 0.80) with poor prognosis (long-term outcome) using clinical scoring system of Bader D et al, (37).

In this study urinary UA/Cr ratio was higher in preterm normal (1.04±0.12). This finding is coincident with that of Orozco-Gregorio et al. (38) who recorded increased levels of urinary uric acid levels in preterm versus term neonates and this was found to be a part of total increase in antioxidants in preterm, this increase persisted till seventh day of life even in absence of oxidant stress. Saugstad (39) strengthened the hypothesis that an oxygen radical disease exists in preterm infants even in absence of asphyxia.

In our study urinary uric acid excretion in mg/dl GFR (Simkin index) was also higher in preterm normal neonates as compared to term babies. This is in agreement with Bhongire et al. (33) who concluded that the more the prematurity the higher the urinary levels of uric acid.
This was explained by Basuet et al.(34) as they speculated that uric acid may be physiologically important as an antioxidant in the epithelial lining fluid of the respiratory tract in preterm neonates during the first weeks of life.

In our current study urinary UA/Cr ratio was higher in asphyxiated preterm cases versus term cases with a mean of 2.6± 0.46 versus 1.2 ±0.87. This is in agreement with Akisu and Kulturusay(40) who showed increased excretion of uric acid in premature asphyxiated babies. Also, Nariman et al(41), had similar results in preterm infants with respiratory distress syndrome(RDS).

Furthermore Patel KP et al(42), demonstrated an association between cerebral ischemia and periventricular leukomalacia with high plasma concentrations of ATP degradation products in preterm babies. Also, Chen and Tsai(36) detected increased serum uric acid levels in preterm babies as a marker of previous asphyxia thus predicting the occurrence of intraventricular Hge.

In our study we found urinary UA/Cr ratio to be sensitive (91.7%), specific (83.3%), of good positive predictive value (84.6%) and accurate (87.5%) in the assessment of perinatal asphyxia.

The urinary uric acid/creatinine ratio allows for the rapid recognition of asphyxia and assessment of its severity and potential for short term morbidity or death as well as the prediction of the long term outcome.

While numerous indicators for asphyxia are recognized, no single indicator has been found to be predictive of subsequent morbidity. The Apgar score have historically been used to define asphyxia and attempt outcome prognostication but proved to be inaccurate(43). Although several biochemical indicators of asphyxia, such as hypoxanthine, brain isoenzyme of creatine phosphokinase, neuron specific enolase, excitatory amino acids, erythropoietin and vasopressin, have been reported, they are most useful as research goals and are not available in most clinical services. However, we found UA/Cr ratio to be a good, simple screening test for the early assessment of perinatal asphyxia. Furthermore, there is a correlation between this ratio and the severity of the encephalopathy and outcome indicating the degree of injury at an early stage when other quantitative methods frequently cannot be carried out.

Conclusion:
We found that UA/Cr ratio level is increased in the asphyxiated newborns in comparison to normal healthy newborns. So, we conclude that UA/Cr ratio could be a useful marker for early diagnosis of HIE in the newborns and also in determining the grade of hypoxia. UA/Cr ratio was found to be very specific in predicting severity of injury, this specificity of UA/Cr ratio is a reflection of its nature as a marker of ischemia.

Therefore, early prediction of HIE can protect asphyxiated neonates from permanent neurological damage, decrease mortalities from HIE.
